

Near-optimal Adaptive Scheduling of Scalable Videos over Wireless Channels

Chao Chen, *Student Member, IEEE*, Robert W. Heath Jr., *Fellow, IEEE*, Alan C. Bovik, *Fellow, IEEE*, and Gustavo de Veciana, *Fellow, IEEE*,

Abstract

We propose two scheduling algorithms that seek to optimize the perceptual quality of scalably coded videos transmitted over slow fading wireless channels. The first scheduling algorithm is derived from a Markov Decision Process (MDP) formulation developed here. We model the dynamics of the channel as a Markov chain and reduce the problem of dynamic video scheduling to a tractable Markov decision problem over a finite state space. Based on the MDP formulation, a near-optimal scheduling policy is computed that maximizes an objective proxy of video quality, the time-average *Multi-Scale Structural SIMilarity* (MS-SSIM) index. Using sights token from the development of the optimal MDP-based scheduling policy, the second proposed scheduling algorithm is an online scheduling method that only requires only easily measurable knowledge of the channel dynamics, and is thus viable in practice. Simulation results show that the performance of both scheduling algorithms is close to a performance upper bound also derived in this paper.

I. INTRODUCTION

Video transmission over wireless channels is a challenging task. The capacity of wireless channels varies over time, making the delivery of real-time video challenging due to tight delay constraints. For example, if the coherence time of the channel is comparable to the delay constraint, then the time-diversity of the channel cannot be exploited. Traditional channel coding methods cannot provide a graceful visual quality degradation of the received video in the presence of deep fades. Adaptive

transmission techniques such as multi-layer scheduling and link-adaptation can be employed to adjust rates to changing channel conditions. Furthermore, video packets are structured. Due to the nature of predictive video coding algorithms, a video frame can be decoded only when its predictors have been received at the receiver. Hence, the prediction structure of the video codec enforces a partial order on the transmissions of the video packets.

Scalable video coding (SVC) is one approach to enable flexible video transmission over channels with varying throughput [1], [2]. An SVC video encoder produces a layered video stream that contains a base layer and several enhancement layers. If the throughput is low, the transmitter can choose to transmit the base layer only, which provides a moderate, but acceptable, degree of visual quality at the receiver. If the channel conditions improve, the transmitter can transmit one, or more, enhancement layers to further improve the visual quality. Conceptually, SVC provides a means to adapt the data rate for wireless video transmission. The wireless transmitter can adapt the data rate by selectively scheduling video data associated with various layers for transmission rather than transcoding the video sequence into a different rate.

Designing scalable video scheduling algorithms for wireless channels is a complex task. The scheduling policy depends, not only on the channel conditions, but also, on the receiver buffer state. For example, if the receiver has successfully buffered base layer data over many frames, the scheduler could choose to transmit some enhancement layer data to improve the video quality even if the throughput is low. At any time, the scheduling decision will determine the receiver buffer state which, in turn, affects the future scheduling decisions. Therefore, adaptive video data scheduling is a sequential decision problem. The most natural way to address such problems is to model the dynamics of the channel as a finite state Markov chain and to employ a Markov decision process (MDP)-based formulation to study scheduling methods. Directly determining an optimal scheduling policy using an MDP formulation is not possible, however, because the system state space is infinitely large (see Section. III-A). Moreover, in a practical wireless network, a model for the dynamics of the channel states is not typically available, which limits the applicability of this approach.

A. Contributions

The objective of this paper is to leverage the MDP framework to develop practical scheduling algorithms and optimize the receiver perceptual video quality for scalable video transmission over wireless channels. First, we propose a tractable MDP formulation based on a reasonable approximation of the state space. Near optimal scheduling policies can be derived from this MDP formulation. Then, we propose a scheduling algorithm that substantially simplifies the MDP-based scheduling policy as

it requires only limited information regarding the channel state dynamics. We prove an upper bound on the achievable video quality of all possible scheduling algorithms. Simulation results show that, under different channel conditions, the performance of proposed scheduling algorithms is indeed very close to the upper bound.

Our contributions made in this paper are:

- 1) *An MDP formulation is proposed to facilitate the design of adaptive scheduling policies.* Typical mobile users usually have an application layer storage space of several gigabytes. Thus, the buffer size can be effectively regarded as infinite. Because the performance of the scheduling policy depends on the receiver buffer state, the policy needs to be optimized over an infinitely large state space and the scheduling problem is intractable. In this paper, by applying reasonable restrictions on the set of scheduling policies considered in our MDP formulation, we prove that optimizing the transmission policy is equivalent to solving a semi-Markov decision problem on a finite state set (see Section. III). Based on this result, near-optimal scheduling policies can be derived using the proposed MDP formulation.
- 2) *A simple and near-optimal scheduling algorithm is proposed.* In most cases, models for channel dynamics are not available. By simplifying the channel model and the scheduling decision of the MDP formulation, we devise an on-line scheduling algorithm which, unlike the MDP-based policy, only requires limited measurable knowledge of the channel dynamics. Simulation results show that the proposed on-line algorithm performs nearly as well as the MDP-based scheduling policy.
- 3) *Performance optimality is justified.* To assess the performance of the proposed scheduling algorithms, an upper bound on the achievable video quality for adaptive scheduling is proved. Simulation results show that both the MDP-based scheduling policy and the proposed on-line scheduling policy perform close to the upper bound.

B. Related Work

Adaptive video data scheduling is an important topic of research [3]–[9]. In [3], adaptive video transmission over a packet erasure channel was studied by modeling the buffer state as a controlled Markov chain. In [4], an MDP-based scheduling algorithm was proposed for video transmission over packet loss networks. This work was further extended for wireless video streaming in [5]. The wireless channel was modeled as a binary symmetric channel. This channel model can only be justified for fast fading channels, where the coherence time is much less than the delay constraint. In that case, interleaving can be applied without violating the delay constraint, and the channel will appear as an i.i.d

channel. For slow fading channels such as those considered here, the bit error rate cannot be modeled as a constant. In [6], [7], and [8], reinforcement learning frameworks were proposed for wireless video transmission. Their proposed algorithms were based on MDP using a discounted-reward maximization formulation. The transmitter learns the characteristics of the channel and the video sequence during the transmission process. The scheduling policy is updated according to the learned characteristics. In our previous work [9], an infinite-horizon average-reward maximization MDP formulation was proposed. The channel and source characteristics, unlike in this paper, were assumed to be known.

The most closely related prior work is [5]–[7] and [8] which focus on single user scalable video transmission over wireless channels. Our work contrasts with these as follows:

- *Channel Characteristics.* We focus on slow-fading wireless channels experienced by pedestrian users. In the channel model of [5], the bit error probability of the channel was assumed constant. This assumption can only be justified for fast fading channels, where the channel coherence time is much less than the delay constraint in video applications. In that case, interleaving can be applied without violating the delay constraint, and the channel will appear to have i.i.d. bit errors. For slow fading channels, where the coherence time is much longer, it is impossible to apply interleaving over many coherence periods due to the delay constraint. In this case, i.i.d. models are no longer suitable because they do not capture information regarding channel variations. By contrast, the algorithm proposed in this paper explicitly considers channel state variation in scheduling.
- *Optimization objective.* Most of the existing MDP-based scheduling algorithms are based on a *utility* function as the optimization objective. The utility function is usually written as a weighted sum of distortion reductions incurred once decoding the received data units. The weights assigned to different data units, to some extent, reflect their importance and inter-dependency, but are heuristically chosen. The resulting utility function cannot accurately indicate the visual quality of played out frames. Here, instead of optimizing a utility function, we directly optimize the visual quality of the video frame played out in each frame slot. The visual quality is measured via the MS-SSIM index which correlates well with human objective judgments [10].
- *Non-availability of channel state dynamics.* In a practical wireless video transmission application, models for the dynamics of the channel state are typically unavailable. To address this problem, a reinforcement learning algorithm can be employed to learn a good policy from making wrong scheduling actions. Video quality, however, will be degraded during the learning period. We propose an adaptive alternative to such reinforcement learning methods, that only uses the channel coherence time and current channel throughput which are easy to measure in practice. The

performance of the proposed algorithm is very close to a derived performance upper bound.

C. Organization of paper

This paper is organized as follows: The system model is introduced in Section II. The assumptions we make about the video codec and the rate-quality model are described in Section II also. In Section III, the MDP formulation and the performance upper bound are proposed. The near-optimal on-line scheduling algorithm is introduced and validated by simulations in Section IV. Section V concludes the paper.

II. SYSTEM MODEL

We first describe the wireless video system to be considered. Then, we present our video codec configuration and introduce the rate-quality model.

We briefly introduce some notations used in the paper. $\mathbf{A}$ and $\mathbf{a}$ are examples of a matrix and a vector, respectively. $\mathcal{A}$ is a set. $|\mathcal{A}|$ is the cardinality of set $\mathcal{A}$. $\lceil \cdot \rceil$ is the ceiling function. $\mathbb{P}(\cdot)$ is the probability measure and $\mathbb{E}[\cdot]$ is the expectation. $\mathbb{N} = \{0, 1, 2, \dots\}$ is the set of non-negative integer numbers. The other frequently used notations are summarized in Table I.

A. System Overview

We consider a time-slotted system that transmits scalable videos over a slow fading wireless channel. The video sequence is encoded with a quality-scalable video encoder and is stored in a video server. The video server transmits video data to a mobile user via a wireless transmitter. Each slot, the server sends some video data upon request of a scheduler at the wireless transmitter. This data is packetized at the wireless transmitter for physical layer transmission. The scheduler operates according to a policy which maps the channel and receiver buffer state to the scheduling action (see Fig. 1).

We assume that the link between the video server and the wireless transmitter is not the bottleneck for transmission to the mobile. Thus, from the perspective of the wireless transmitter, the whole video sequence is available for transmission. We also assume that the physical layer channel state information is available at the transmitter and that the modulation and coding scheme (MCS) is determined by a given physical layer link-adaptation policy.

B. Video Codec Configuration

We assume that the video sequence is encoded by an H.264/SVC-compatible scalable video encoder. The duration of each frame ΔT is called a frame slot. The video frames are uniformly partitioned into

Groups of Pictures (GOPs). Every GOP has F_{GOP} frames. The first frame in a GOP is an I frame while the other frames are P frames. Every frame is encoded into L layers. The first layer is the base layer; the other layers are enhancement layers. Every enhancement layer of a frame is predictively encoded using the lower layers of the frame. The base layer of a P frame is predictively encoded using the base layer of its preceding frame. The base layer of an I frame is encoded independently (see Fig. 2).

Each frame has a playout deadline at the receiver. In the following, frames whose deadlines have expired are called expired frames, otherwise they are said to be active frames. The first active frame is called the “current frame”. At any point in time, frames are indexed relative to the current frame as shown in Fig. 2. The video data in the ℓ^{th} layer of the f^{th} frame is called the $(f, \ell)^{\text{th}}$ **video data unit**.

We adopt the prediction structure in Fig. 2 rather than the “Hierarchical B” structure because no structural delay is introduced [1]. In the “Hierarchical B” prediction structure, the encoding order differs from the display order, thus the transmission of a frame must be delayed until all necessary predictors are received. Besides, because the enhancement layers are used to predict other frames in the “Hierarchical B” structure, dropped enhancement layers can give rise to error propagation and unpredictable visual quality degradation. At the possible cost of lower compression efficiency, the prediction structure that we use eliminates error propagation arising from *enhancement* layer losses, since there is no inter-frame prediction among enhancement layers.

C. Rate-Quality Model

Let z_f be the amount of received data for the f^{th} frame. The rate-quality function $q_f(z_f)$ captures the quality of the frame when it is decoded. Let $\omega_{(f,\ell)}$ be the amount of data in the $(f, \ell)^{\text{th}}$ data unit and $q_{(f,\ell)}$ be the visual quality *increment* if the ℓ^{th} layer is correctly received, given all its predictors have also been received. As illustrated in Fig. 3, since a data unit can be decoded only when all its associated data has been received, $q_f(z_f)$ is a piecewise constant and right-continuous function with jumps at $z_f = \sum_{\ell=1}^m \omega_{(f,\ell)}$, $m = 1, 2, \dots, L$. Thus $q_{(f,\ell)}$ and $\omega_{(f,\ell)}$ characterize $q_f(z_f)$.

In a real video sequence, for a given layer ℓ , the rate-quality characteristics $q_{(f,\ell)}$ and $\omega_{(f,\ell)}$ vary across frames. In this paper, we adopt a simple model to approximate $q_f(z_f)$. Let n be the number of frames in a video sequence. Since for each layer, $q_{(f,\ell)}$ is almost the same for all frames, we use $q^\ell = 1/n \sum_{f=1}^n q_{(f,\ell)}$ as an estimate for visual quality *increment* if the ℓ^{th} layer is correctly received. We also assume that $\omega_{(f,\ell)}$ is almost the same for I frames and P frames, respectively. Thus, let ω_ℓ^I and ω_ℓ^P be the average values of $\omega_{(f,\ell)}$ across the video for I frames and P frames, respectively.

Our rate-quality models $q^I(z_f)$ and $q^P(z_f)$ for I frames and P frames are respectively constructed as piecewise constant functions with jumps at $z_f = \sum_{\ell=1}^m \omega_\ell^I$ and $z_f = \sum_{\ell=1}^m \omega_\ell^P$, $m = 1, 2, \dots, L$.

Conventional image quality measures such as the PSNR reflect absolute signal fidelity but without accounting for perceptual visual quality. Recently, a variety of models that accurately predict perceptual video quality have been proposed [11]–[15]. In our formulation, we adopt the MS-SSIM index as the visual quality measure [11], since it has been shown to correlate quite well with perceptual visual quality and it is of reasonable computational complexity [10].

The MS-SSIM index of a video sequence ranges from 0 to 1. The larger the index, the better the quality. In our rate-quality model, the marginal quality increment q^ℓ is measured using the MS-SSIM index. Larger values of q^ℓ mean a larger marginal improvement can be achieved by transmitting the ℓ^{th} layer data units.

D. Streaming Setup

We focus on scheduling for a slow fading channel. By slow fading, we mean that the coherence time of the channel is less than the duration of a GOP and larger than the duration of a frame. Assuming the mobile users are moving in a 1.5m/s walking speed and the carrier frequency is 2GHz, the Doppler spread is about 10Hz. The coherence time is about 100ms. A typical GOP duration is about 1 second and a frame slot is about 30ms. Hence, for pedestrian video users, wireless channels are slow fading.

As the channel state is stable during each frame slot, the scheduling decision is made on a frame-by-frame basis. At the beginning of each frame slot, a frame is played out, and video data units are scheduled for transmission. The scheduling action is defined as a set of ordered video data units

$$\mathcal{U} = \{(f_1, \ell_1), (f_2, \ell_2), \dots, (f_{|\mathcal{U}|}, \ell_{|\mathcal{U}|})\}. \quad (1)$$

When scheduling action $\mathcal{U}$ is taken, the associated data units are transmitted sequentially. Each scheduled data unit is packetized into physical layer packets and each packet is repeatedly transmitted, i.e., if errors occur, until acknowledged.

III. MARKOV DECISION PROCESS-BASED MODEL

In this section, we propose an MDP-based model to determine the near-optimal scheduling policy. To that end we describe the scheduler's state space and the policies to be considered. We then show how to reduce the scheduling problem to a finite-state Markov decision problem using reasonable approximations. To validate the optimality of the MDP-based scheduling policies, we develop a performance upper bound at the end of this section.

A. Scheduling Policy and State Space

Considering all possible scheduling actions makes defining the scheduling policy and representing the buffer state unmanageably complex. On one hand, to capture the buffer state, the frame index and the layer index of each received data unit need to be recorded. If we assume an infinite playback buffer, the number of received data units is not bounded. So we cannot represent all possible buffer states using a finite-dimensional space. On the other hand, we note that not all possible scheduling policies need to be considered. For example, video data units should not be transmitted before their predictors. If their predictors are not received before their playout deadlines, these units are undecodable and useless. Thus we need only consider those scheduling strategies that are not dominated and have potential to achieve good performance.

Specifically, we consider scheduling policies under the following assumptions:

Assumption 1: The scheduler always schedules a data unit for transmission after its predictors.

Assumption 2: The amount of video data scheduled on a slot exceeds the amount of data which can be transmitted in the slot.

Assumption 3: Let $\mathcal{W}$ denote the set of data units associated with the first W active frames. We assume the scheduler first sends the video data in $\mathcal{W}$. Then, if all the data in $\mathcal{W}$ has been received, the policy greedily schedules as many enhancement layers as possible, i.e., starts transmitting the next frame only when all the layers of preceding frame have been received.

Assumption 4: The scheduler never schedules enhancement layer data units for future P frames if those for earlier P frames in the same GOP have not been sent.

Assumption 1 ensures that the transmission order is compatible with the prediction order given in Section II-B, since a data unit can be decoded only when its predictors are received. Assumption 2 ensures the transmitter will not be idle during a slot. Assumption 3 stems from the fact that, when many frames are buffered at the receiver, the scheduler can transmit more enhancement layers because there is sufficient time before the frames are played out. As will be discussed in Section III-C, this assumption helps to simplify the policy optimization problem. It should be noted that policies under Assumption 3 are different from the sliding window policies defined in [4]. Indeed, our scheduling policy allows the transmitter to transmit data units outside the window. With Assumption 4 in effect, at any time and for all the P frames in a GOP, the scheduler does not sacrifice the quality of the frames that will be displayed sooner for the frames to be displayed later by transmitting more enhancement layer data for the latter. Because the optimization objective is the time-average MS-SSIM index, the rate-quality function of each P frame is assumed to be the same and thus their qualities are equally

important. Transmitting more enhancement layer data for later frames does not help to improve the time-average MS-SSIM value.

Note that, although the P frames within a GOP are equally important in terms of contribution to the time-average MS-SSIM index, the I and P frames in different GOPs are not. For example, when the channel throughput is very low, it may be beneficial to sacrifice P frames in the current GOP in order to transmit the base layer for an I frame in the next GOP, because an I frame contains much more data than a P frame and the loss of an I frame would cause severe decoding failures throughout the next GoP. To differentiate the importance of current and future GOPs, we partition the data units of the active frames into three sets: $\mathcal{I}$, $\mathcal{I}^{\text{pre}}$ and $\mathcal{I}^{\text{post}}$. The set $\mathcal{I}$ contains the data units of the first active I frame, $\mathcal{I}^{\text{pre}}$ contains data units preceeding the first active I frame, and $\mathcal{I}^{\text{post}}$ contains the remaining active data units (see Fig. 4).

We define the overall buffer state space $\mathcal{V}$ via three sets $\mathcal{V}^{\text{I}}$, $\mathcal{V}^{\text{pre}}$ and $\mathcal{V}^{\text{post}}$, where $\mathcal{V} = \mathcal{V}^{\text{I}} \times \mathcal{V}^{\text{pre}} \times \mathcal{V}^{\text{post}}$.

$\mathcal{V}^{\text{I}}$: The state of $\mathcal{I}$ is defined as $\mathbf{v}^{\text{I}} = (f^{\text{I}}, b^{\text{I}})$, where $f^{\text{I}} \in \{1, \dots, F_{\text{GOP}}\}$ is the number of frames until the first active I frame and b^{I} is the number of the received data units of $\mathcal{I}$, thus $\mathcal{V}^{\text{I}} = \{1, \dots, F_{\text{GOP}}\} \times \{1, \dots, L\}$.

$\mathcal{V}^{\text{pre}}$: When Constraint 4 is enforced, the number of data units received in $\mathcal{I}^{\text{pre}}$ must be non-increasing in the frame index. Hence, we only need record the total number of received data units for each layer. We define the buffer state space for $\mathcal{I}^{\text{pre}}$ as a L -dimensional vector $\mathbf{v}^{\text{pre}} = (b_1^{\text{pre}}, b_2^{\text{pre}}, \dots, b_L^{\text{pre}})$, where b_ℓ^{pre} is the number of the received data units in ℓ^{th} layer for $\mathcal{I}^{\text{pre}}$, thus $\mathcal{V}^{\text{pre}} = \{0, 1, \dots, F_{\text{GOP}} - 1\}^L$.

$\mathcal{V}^{\text{post}}$: As with $\mathcal{V}^{\text{pre}}$, we define the buffer state space of $\mathcal{I}^{\text{post}}$ as a L -dimensional vector $\mathbf{v}^{\text{post}} = (b_1^{\text{post}}, b_2^{\text{post}}, \dots, b_L^{\text{post}})$, where b_ℓ^{post} is the number of the received data units in the ℓ^{th} layer of $\mathcal{I}^{\text{post}}$. Because the receiver buffer size is assumed to be large, i.e., essentially infinite, b_ℓ^{post} is unbounded. Thus $\mathcal{V}^{\text{post}} = \mathbb{N}^L$, where $\mathbb{N} = \{0, 1, \dots, \infty\}$.

In [16] and [17], it is shown that a first-order finite state Markov chain (FSMC) can be utilized to describe the first-order channel state transition probabilities for Rayleigh fading channels. First-order FSMC models have also been validated in [18] and [19] by wireless channel measurements in urban areas. In our MDP-based model, we employ a first-order FSMC to describe the dynamics of the channel state.

At the physical layer, the transmission bit rate x is determined by the modulation and coding

scheme (MCS) and the packet error rate y is determined by both the channel state and the MCS¹. We assume the chosen MCS is a function of the channel state under a given link adaptation mechanism. For example, the physical layer can always choose the MSC which maximizes channel throughput $x(1 - y)$. Thus, there is a one-to-one mapping from channel state to the tuple (x, y) . We define the channel state as $\mathbf{c} = (x, y)$. Due to the Markov property of the channel state, channel state can also be modeled by an FSMC. The channel state space is $\mathcal{C} = \{\mathbf{c}^1, \dots, \mathbf{c}^{|\mathcal{C}|}\}$, where $\mathbf{c}^i = (x^i, y^i)$ is the i^{th} channel state. The state transition matrix $\mathbf{P}^c$ is a $|\mathcal{C}| \times |\mathcal{C}|$ matrix with entry $\mathbf{P}_{i,j}^c = \mathbb{P}(\mathbf{c}^j | \mathbf{c}^i)$ being the transition probability from state $\mathbf{c}^i$ to $\mathbf{c}^j$.

The system state space $\mathcal{S}$ is defined as the product of the channel state space $\mathcal{C}$ and the buffer state space $\mathcal{V}$. For each state $\mathbf{s} \in \mathcal{S}$, we define a feasible control set $\mathcal{U}_{\mathbf{s}}$ that contains all the scheduling actions (see Equation (1)) complying with all the four assumptions. The state $\mathbf{s}$ contains all the information about the receiver buffer and the channel. The transmitter must decide which action in $\mathcal{U}_{\mathbf{s}}$ to take in order to maximize the time-average MS-SSIM index value. We define the scheduling policy $\mu(\cdot)$ as the mapping from the system state $\mathbf{s}$ to an action in $\mathcal{U}_{\mathbf{s}}$. In the following sections, we show how to optimize the scheduling policy $\mu(\cdot)$.

B. Optimization Objective

Since the channel condition is modeled as a random process, we denote by $(C_t, V_t, S_t)_{t \in \mathbb{N}}$ the random processes modeling channel, buffer and system state, respectively. Accordingly, we denote by $(\mathbf{c}_t, \mathbf{v}_t, \mathbf{s}_t)_{t \in \mathbb{N}}$ their realizations. At the beginning of each time slot t , the first frame in the window is played out and the MS-SSIM index is

$$q(S_t) = \sum_{\ell=1}^L q^\ell \times \mathbb{1}_\ell(S_t), \quad (2)$$

where $\mathbb{1}_\ell(S_t)$ is the indicator that the ℓ^{th} layer of the displayed frame is available in state S_t . The quantity q^ℓ is the marginal video quality improvement if, in addition to layers $1, 2, \dots, \ell - 1$, layer ℓ is available (see Section II-C). Our aim is to find an optimal policy $\mu^*(\cdot)$ which maximizes the time-average MS-SSIM index, i.e.,

$$J_\mu = \lim_{n \rightarrow \infty} \mathbb{E}_\mu \left\{ \frac{1}{n} \sum_{t=0}^{n-1} q(S_t) \right\}. \quad (3)$$

¹Here, bit rate x is the number of bits transmitted in a time slot ΔT , i.e., the transmission rate normalized with slot duration ΔT .

C. Finite State Problem Formulation

Since the state space $\mathcal{V}^{\text{post}}$ is infinite, the state space $\mathcal{S}$ is also infinite. Optimizing the scheduling policy over this infinite-state space is intractable. With Assumption 3, the scheduling policy is actually fixed when all the data in window $\mathcal{W}$ is received. We only need to determine the optimal scheduling policy for states where some of the video data in the window has not been received, which is a finite state set. The system state, however, still evolves in the infinite state space $\mathcal{S}$. In the following, we show how to simplify this infinite state space problem to a finite-state problem.

We define the set of states where some of the video data in $\mathcal{W}$ has not been received as follows:

$$\mathcal{S}_W = \{s | s \in \mathcal{S}, \mathcal{O}(s) \subset \mathcal{W}\}, \quad (4)$$

where $\mathcal{O}(s)$ is the set of buffered active video data units when the state is s . We define another subset of $\mathcal{S}$ as follows

$$\mathcal{S}_{\overline{W}} = \{s | s \in \mathcal{S}, \mathcal{W} \subseteq \mathcal{O}(s)\}. \quad (5)$$

For all the states in $\mathcal{S}_{\overline{W}}$, all the video data units in $\mathcal{W}$ has been received. Note that, under Assumption 3, the video scheduler focuses on transmitting data in $\mathcal{W}$ until $\mathcal{W} \subseteq \mathcal{O}(s)$. Thus $\mathcal{S}_W$ and $\mathcal{S}_{\overline{W}}$ form a partition of state space $\mathcal{S}$. In other words, we have $\mathcal{S}_W \cup \mathcal{S}_{\overline{W}} = \mathcal{S}$ and $\mathcal{S}_W \cap \mathcal{S}_{\overline{W}} = \emptyset$.

Given a policy $\mu(\cdot)$, the system state evolves as a Markov chain in set $\mathcal{S}_W \cup \mathcal{S}_{\overline{W}}$. Because the transmission rate is finite, the number of states in $\mathcal{S}_{\overline{W}}$ which can be reached from $\mathcal{S}_W$ in one step is also finite. We formally define this set of states as follows

$$\mathcal{S}_\Delta = \{s | s \in \mathcal{S}_{\overline{W}}; \exists s' \in \mathcal{S}_W, \text{ s.t., } \mathbb{P}_\mu(s|s') > 0\}, \quad (6)$$

where $\mathbb{P}_\mu(s|s')$ is the state transition probability under policy μ (for the expression for $\mathbb{P}_\mu(s|s')$, see Appendix. A). Thus to move from $\mathcal{S}_W$ into the set $\mathcal{S}_{\overline{W}}$, the system state first hits a state in $\mathcal{S}_\Delta$ and then stays in $\mathcal{S}_{\overline{W}}$ for some time. During this period, the decoded video quality is always $\sum_{\ell=1}^L q^\ell$, because all the layers in $\mathcal{W}$ are available. The evolution of the system when it moves into set $\mathcal{S}_{\overline{W}}$ affect the performance of the system. In general, the longer it stays in $\mathcal{S}_{\overline{W}}$, the better the performance is. Although the scheduling policy in $\mathcal{S}_{\overline{W}}$ is fixed as described in Assumption 3, the policy in $\mathcal{S}_W$ determines how frequently the system state will hit $\mathcal{S}_{\overline{W}}$ and thus critically impacts the system performance.

In the following, we denote the system under a given policy μ as system Π_μ . Let $t_\mu(s)$ be the expected time spent by Π_μ in $\mathcal{S}_{\overline{W}}$ after it enters $\mathcal{S}_{\overline{W}}$ at state $s \in \mathcal{S}_\Delta$. Let $\tilde{\mathbb{P}}_\mu(s'|s)$ denote the probability that Π_μ jumps back to $\mathcal{S}_W$ at state $s' \in \mathcal{S}_W$ after it enters $\mathcal{S}_{\overline{W}}$ at state s . To find the optimal policy, we define a finite-state system $\tilde{\Pi}_\mu$ as follows:

Definition 1: A system $\tilde{\Pi}_\mu$ is called the simplified system of the original system Π_μ if it has the following dynamics:

- 1) The system is a semi-Markov process over state space $\tilde{\mathcal{S}} = \mathcal{S}_W \cup \mathcal{S}_\Delta$. In any state $\mathbf{s} \in \tilde{\mathcal{S}}$, the visual quality is $q(\mathbf{s})$ as in (2). In any state in $\mathcal{S}_W$, the system evolves according to the policy μ . The system state transition probability is $\mathbb{P}_\mu(\cdot|\cdot)$.
- 2) When the system jumps to a state $\mathbf{s} \in \mathcal{S}_\Delta$, it spends $t_\mu(\mathbf{s})$ slots in $\mathbf{s}$ with video quality $\sum_{\ell=1}^L q^\ell$ for each slot. The system then transitions to a state $\mathbf{s}' \in \mathcal{S}_W$ with probability $\tilde{\mathbb{P}}_\mu(\mathbf{s}'|\mathbf{s})$ (see Fig. 5).

It should be noted that $\tilde{\Pi}_\mu$ is not coupled with the original system Π_μ . It just shares some properties with the original system. The following theorem relates the visual quality under $\tilde{\Pi}_\mu$ and that of Π_μ .

Theorem 1: If the jump chain of the original system Π_μ is positive recurrent, then the time-average MS-SSIM index of Π_μ is the same as the simplified system $\tilde{\Pi}_\mu$.

Proof Sketch: If the jump chain is positive recurrent, the jump from $\mathcal{S}_W$ to $\mathcal{S}_\Delta$ can partition the Markov process into i.i.d segments. We only need to optimize the policy μ to maximize the average quality in each segment. Every segment consists of two consecutive subsegments. During the first subsegment, $\mathbf{s}_t \in \mathcal{S}_{\bar{W}}$. In the other subsegment, $\mathbf{s}_t \in \mathcal{S}_W$. Because every state in $\mathcal{S}_{\bar{W}}$ has the same visual quality $\sum_{\ell=1}^L q^\ell$, we can abstract the first subsegment as a single state with transition probability $\tilde{\mathbb{P}}_\mu(\cdot|\cdot)$. This simplified system provides the same average quality as the original system. For a detailed proof, see the technical report [20]. ■

Remark The positive recurrent condition for the jump chain means that the average throughput of the channel is neither too large nor too small relative to the average data rate of the video. If the average throughput of the channel is very large, the receiver buffer can always buffer enough frames and dynamic scheduling is unnecessary. If the average channel throughput is too small, the channel cannot support the video stream and dynamic scheduling cannot help either.

As indicated by Theorem 1, given any policy μ , the visual quality of Π_μ is the same as $\tilde{\Pi}_\mu$. Thus, we can optimize our policy with respect to $\tilde{\Pi}_\mu$ which has a finite-state space, and a standard policy optimization algorithm can be applied.

Before we can apply an MDP algorithm to optimize the policy, we need to compute $t_\mu(\mathbf{s})$ and $\tilde{\mathbb{P}}_\mu(\mathbf{s}'|\mathbf{s})$ for every state $\mathbf{s} \in \mathcal{S}_\Delta$ and $\mathbf{s}' \in \mathcal{S}_W$. Both $t_\mu(\mathbf{s})$ and $\tilde{\mathbb{P}}_\mu(\mathbf{s}'|\mathbf{s})$ only involve dynamics of the system in $\mathcal{S}_{\bar{W}}$. Details on how to compute $t_\mu(\mathbf{s})$ and $\tilde{\mathbb{P}}_\mu(\mathbf{s}'|\mathbf{s})$ are found in Appendix B.

D. Determining Optimal Policy via Value Iteration

Given $t_\mu(\cdot)$ and $\tilde{\mathbb{P}}_\mu(\cdot|\cdot)$, the optimal policy for an MDP can be determined for the simplified system $\tilde{\Pi}_\mu$, which is also the optimal policy of Π_μ . Let $\mathbf{s}_{\text{ini}}$ be any state in $\tilde{\mathcal{S}} = \mathcal{S}_W \cup \mathcal{S}_\Delta$. The hitting time to state $\mathbf{s}_{\text{ini}}$ can partition the process into i.i.d cycles. Optimizing the policy $\mu(\cdot)$ in the cycles maximizes the time-average MS-SSIM index of the system. Similar to the derivation in [21, p. 441], this is equivalent to an average-reward maximization problem with stage-reward $g(\mathbf{s}) - \eta(\mathbf{s})\lambda$, where λ is the expected average-reward of each cycle and

$$g(\mathbf{s}) = \begin{cases} q(\mathbf{s}) & : \mathbf{s} \in \mathcal{S}_W \\ t_\mu(\mathbf{s}) \sum_{\ell=1}^L q^\ell & : \mathbf{s} \in \mathcal{S}_\Delta, \end{cases}$$

$$\eta(\mathbf{s}) = \begin{cases} 1 & : \mathbf{s} \in \mathcal{S}_W \\ t_\mu(\mathbf{s}) & : \mathbf{s} \in \mathcal{S}_\Delta, \end{cases}$$

where $q(\mathbf{s})$ is defined in (2). Let us denote by $h(\mathbf{s})$ the average reward-to-go in each cycle when the system starts at state $\mathbf{s}$. Then we have the following Bellman's equation array:

$$h(\mathbf{s}) = g(\mathbf{s}) - \eta(\mathbf{s})\lambda + \sum_{\mathbf{s}' \in \mathcal{S}_W \cup \mathcal{S}_\Delta} \mathbb{P}_\mu(\mathbf{s}'|\mathbf{s})h(\mathbf{s}'), \quad (7)$$

where $h(\mathbf{s}_{\text{ini}}) = 0$. To find the optimal policy, the standard value iteration algorithm can be applied [21, p. 430].

On the one hand, the assumptions on scheduling policy result in the finite state MDP-based formulation. On the other hand, the assumptions may render the derived scheduling policy sub-optimal. To verify the performance of the scheduling policy derived from the MDP formulation is actually close to optimal, we prove a performance upper bound in the next section.

E. Performance Upper Bound

In the rest of the paper, let $R_t = X_t(1 - Y_t)$ be the throughput of the channel at time t , where X_t is the transmission bitrate and Y_t is the packet error rate as defined in Section. III-A. Since the channel condition is modeled as a random process, X_t , Y_t and R_t are random processes and we will denote by x_t , y_t and r_t their realizations. As discussed in Section. II-C, $q^I(z_t)$ and $q^P(z_t)$ are the rate quality models of I frames and P frames, respectively. Let $\mathbb{1}_t^I$ be the indicator that the t^{th} frame is an I frame. The time-average MS-SSIM of the transmitted video can be written as $\frac{1}{n} \sum_{t=1}^n [q^I(z_t)\mathbb{1}_t^I + q^P(z_t)(1 - \mathbb{1}_t^I)]$, where n is the number of frames in the video sequence. An upper

bound on the performance of any scheduler is given by the following offline optimization problem:

$$\begin{aligned} & \underset{z_{1:n}}{\text{maximize}} \quad \frac{1}{n} \sum_{t=1}^n [q^I(z_t) \mathbb{1}_t^I + q^P(z_t)(1 - \mathbb{1}_t^I)] \\ & \text{s.t.} \quad \frac{1}{t} \sum_{i=1}^t z_i \leq \frac{1}{t} \sum_{i=1}^t r_i, \quad \forall t \in \{1, 2, \dots, n\}, \end{aligned} \quad (8)$$

where the constraint $\frac{1}{t} \sum_{i=1}^t z_i \leq \frac{1}{t} \sum_{i=1}^t r_i$ guarantees that the received data for the frames displayed before time t does not exceed the cumulative throughput prior to time t . We can further relax the constraints in (8) by only keeping the last one, i.e., when $t = n$. The relaxed optimization problem is then given by

$$\begin{aligned} & \underset{z_{1:n}}{\text{maximize}} \quad \frac{1}{n} \sum_{t=1}^n [q^I(z_t) \mathbb{1}_t^I + q^P(z_t)(1 - \mathbb{1}_t^I)] \\ & \text{s.t.} \quad \frac{1}{n} \sum_{t=1}^n z_t \leq \frac{1}{n} \sum_{t=1}^n r_t. \end{aligned} \quad (9)$$

Let $\widehat{q}^I(z_t)$ and $\widehat{q}^P(z_t)$ be the concave envelope of $q^I(z_t)$ and $q^P(z_t)$ respectively (see Fig. 3). Since, $q^I(z_t)$ and $q^P(z_t)$ are upper bounded by $\widehat{q}^I(z_t)$ and $\widehat{q}^P(z_t)$, we can bound problem (9) by:

$$\begin{aligned} & \underset{z_{1:n}}{\text{maximize}} \quad \frac{1}{n} \sum_{t=1}^n [\widehat{q}^I(z_t) \mathbb{1}_t^I + \widehat{q}^P(z_t)(1 - \mathbb{1}_t^I)] \\ & \text{s.t.} \quad \frac{1}{n} \sum_{t=1}^n z_t \leq \frac{1}{n} \sum_{t=1}^n r_t. \end{aligned} \quad (10)$$

Let $n^I = \sum_{t=1}^n \mathbb{1}_t^I$ denote the number of I frames and $n^P = \sum_{t=1}^n (1 - \mathbb{1}_t^I)$ denote the number of P frames. Since the functions $\widehat{Q}^I(z_t)$ and $\widehat{Q}^P(z_t)$ are concave, by Jensen's inequality, we have

$$\frac{1}{n^I} \sum_{t=1}^n \widehat{q}^I(z_t) \mathbb{1}_t^I \leq \widehat{q}^I \left(\frac{1}{n^I} \sum_{t=1}^n z_t \mathbb{1}_t^I \right)$$

and

$$\frac{1}{n^P} \sum_{t=1}^n \widehat{q}^P(z_t)(1 - \mathbb{1}_t^I) \leq \widehat{q}^P \left(\frac{1}{n^P} \sum_{t=1}^n z_t(1 - \mathbb{1}_t^I) \right).$$

Problem (10) can then be bounded by:

$$\begin{aligned} & \underset{z_{1:n}}{\text{maximize}} \quad \frac{n^I}{n} \widehat{q}^I \left(\frac{1}{n^I} \sum_{t=1}^n z_t \mathbb{1}_t^I \right) + \frac{n^P}{n} \widehat{q}^P \left(\frac{1}{n^P} \sum_{t=1}^n z_t(1 - \mathbb{1}_t^I) \right) \\ & \text{s.t.} \quad \frac{n^I}{n} \left(\frac{1}{n^I} \sum_{t=1}^n z_t \mathbb{1}_t^I \right) + \frac{n^P}{n} \left(\frac{1}{n^P} \sum_{t=1}^n z_t(1 - \mathbb{1}_t^I) \right) \leq \frac{1}{n} \sum_{t=1}^n r_t. \end{aligned} \quad (11)$$

If the video is reasonably long, e.g. several minutes, the frame number n will be very large. If we let $n \rightarrow \infty$ and assume the channel throughput r_t is ergodic, $\frac{1}{n} \sum_{t=1}^n r_t$ will converge to the ergodic

capacity $r_{avg} = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{t=1}^n r_t$. Furthermore, since F_{GOP} is the length of the GOP, $\frac{1}{F_{GOP}}$ and $1 - \frac{1}{F_{GOP}}$ are proportion of I and P frames in the video sequences. Thus we have $\frac{n^I}{n} \rightarrow \frac{1}{F_{GOP}}$ and $\frac{n^P}{n} \rightarrow 1 - \frac{1}{F_{GOP}}$. Similarly, for stationary policies², the limits $z^I = \lim_{n \rightarrow \infty} \frac{1}{n^I} \sum_{t=1}^n z_t \mathbb{1}_t^I$ and $z^P = \lim_{n \rightarrow \infty} \frac{1}{n^P} \sum_{t=1}^n z_t (1 - \mathbb{1}_t^I)$ exist. We have $\lim_{n \rightarrow \infty} \left[\frac{n^I}{n} \left(\frac{1}{n^I} \sum_{t=1}^n z_t \mathbb{1}_t^I \right) + \frac{n^P}{n} \left(\frac{1}{n^P} \sum_{t=1}^n z_t (1 - \mathbb{1}_t^I) \right) \right] = \frac{1}{F_{GOP}} z^I + \left(1 - \frac{1}{F_{GOP}} \right) z^P$. Thus, we have shown the following theorem:

Theorem 2: For ergodic wireless throughput and stationary adaptive scheduling policies the following optimization gives an upper bound on performance:

$$\begin{aligned} \underset{z_I, z_P}{\text{maximize}} \quad & \frac{1}{F_{GOP}} \widehat{q}^I(z_I) + \left(1 - \frac{1}{F_{GOP}} \right) \widehat{q}^P(z_P) \\ \text{s.t.} \quad & \frac{1}{F_{GOP}} z_I + \left(1 - \frac{1}{F_{GOP}} \right) z_P \leq r_{avg}. \end{aligned} \tag{12}$$

Since the rate-quality functions $\widehat{q}^I(\cdot)$ and $\widehat{q}^P(\cdot)$ are assumed to be concave, the above optimization problem is convex and easily solved. In Section III-F, this upper bound will be employed as a benchmark to evaluate the performance of our MDP-based scheduling policy.

F. Performance evaluation of the MDP-based scheduling policy

In this section, we evaluate the performance of the policy obtained from our MDP-based formulation. Parallel to [6] and [22], we employ the FSMC channel model proposed in [16] to model the dynamics of Rayleigh fading channels. The SNR at the receiver is partitioned into 4 regions using the algorithm proposed in [16]. In our simulations, we set average SNR to $\Lambda_{avg} = 10\text{dB}$. The MDP-based scheduling algorithm was evaluated on test sequences “foreman”, “bus”, “flower”, “mobile” and “Paris” [23]. These video sequences were encoded using H.264/SVC reference software JSVM [24] with 3 layers. For each sequence, 200 transmissions were sent over the simulated channel. A startup delay constraint was fixed to 100ms, i.e., video playback began 3 frames after the transmission began. To conceal errors, every lost frame was reconstructed by copying the preceding frame. For more details about the FSMC channel model and encoding parameter of the video sequences, see Appendix C.

The performance of the on-line scheduling algorithm was tested over the simulated Markov channel models with different Doppler frequencies ($f_d = 5\text{Hz}$ and 3Hz , respectively). The simulation results are summarized in Table III and Table IV. The time-averaged MS-SSIM value is converted to Difference Mean Opinion Score (DMOS) using the following mapping

$$DMOS = 13.3442 \ln(1 - SSIM) + 3.6226(1 - SSIM) + 77.0117. \tag{13}$$

²A policy is called stationary if it is a function of state $\mathbf{s}$ and the function is invariant with respect to time t .

Equation (13) is obtained by logistic regression using the MS-SSIM indices and MOS values of the images in the LIVE database [25]. DMOS ranges from 0 to 100. Value 0 means perfect visual quality and value 100 means bad visual quality. Roughly speaking, value 50 means fair quality. It can be seen from Table III and Table IV that the DMOS value of the MDP-based scheduling policy is worse than the performance bound by at most 4, which is visually insignificant. Given that the bound given by Theorem 2 is an upper bound (i.e. a lower bound of DMOS value), the MDP-based scheduling policy is indeed near-optimal.

IV. NEAR-OPTIMAL HEURISTIC ON-LINE SCHEDULING ALGORITHM

Although the MDP-based formulation makes it possible to compute a good scheduling policy using value iteration algorithm, off-line computation of such policies requires *a priori* knowledge of the channel dynamics. This motivated us to design a simple on-line scheduling policy which delivers similar performance as the MDP-based policy that only requires little *a priori* knowledge about the channel dynamics.

Basically, a good online video scheduling algorithm should explicitly take advantage of the channel dynamics and schedule data from different quality layers as a function of the receiver buffer state. There are three fundamental questions in designing such a scheduler: 1) How should one incorporate limited knowledge of channel dynamics in adaptive scheduling; 2) How should one determine the number of enhancement layers to schedule; 3) How should one allocate appropriate transmission rate among $\mathcal{I}^{\text{pre}}$, $\mathcal{I}$ and $\mathcal{I}^{\text{post}}$ (see definition in III-A). In the following, we will show how to address these fundamental problems by reasonably simplifying the MDP-based scheduling algorithm.

A. Channel Model Simplification

In a practical wireless communication environment, accurate channel dynamics models such as the state transition probability $\mathbf{P}^c$ are not generally available. Some basic characteristics for the channel dynamics can however be easily referred. At any slot t , the instantaneous channel throughput $r_t = x_t(1 - y_t)$ can be derived using receiver channel state information feedback. The ergodic channel throughput r_{avg} can be estimated by averaging r_t over time. Furthermore, the temporal correlation coefficient $\rho = \frac{\text{cov}(R_t, R_{t+1})}{\sigma(R_t)\sigma(R_{t+1})}$ can also be estimated from r_t . Further it is reasonable to assume the channel throughput R_t will typically regress to the mean r_{avg} . This inspires us to use a simple autoregressive model to capture the dynamics of the channel. The simplest model for R_t is the first order autoregressive model (AR(1)) as follows:

$$R_t - \phi R_{t-1} = c + N_t, \quad (14)$$

where N_t is an i.i.d random variable with zero mean value. From (14), parameter c and ϕ can be estimated as $\phi = \rho$ and $c = r_{avg}(1 - \rho)$. Thus, we have

$$R_t - \rho R_{t-1} = r_{avg}(1 - \rho) + N_t. \quad (15)$$

Using this autoregressive model, the amount of data that will be delivered in the next τ slots by the channel can be estimated as

$$d(r_t) = \mathbb{E} \left[\sum_{j=0}^{\tau-1} R_{t+j} \middle| R_t = r_t \right] = \sum_{j=0}^{\tau-1} [r_t \rho^j + r_{avg}(1 - \rho^j)]. \quad (16)$$

To obtain an accurate estimate in the near future, we set the length of the window τ into the future that will be considered to be the relaxation time³ of the channel, i.e., $\tau = \lceil -(\ln \rho)^{-1} \rceil$. In the following, we use this to determine which quality layers to schedule.

B. Layer Selection

Given the current channel state, receiver buffer state, and estimated available capacity for a window τ into the future, the goal is to determine which layers to schedule. We will focus on determining the number of enhancement layers which should be scheduled. We denote by $L^{\text{sch}}(\mathbf{s}_t)$ the number of layers to be scheduled if the state is $\mathbf{s}_t$. Once $L^{\text{sch}}(\mathbf{s}_t)$ is determined, the online scheduling algorithm only schedules data units from the first $L^{\text{sch}}(\mathbf{s}_t)$ layers.

The layer selection scheme for our proposed on-line algorithm is motivated by that of the MDP-based policy. Using $d(r_t)$ defined in (16), we can estimate the amount of data which can be delivered in the next τ slots. Let $\Gamma(\ell, \mathbf{s}_t)$ be the amount of data which is not currently available at the playback buffer at time t , and belongs to the first ℓ layers of the next τ frames. The quantities $d(r_t)$ and $\Gamma(\ell, \mathbf{s}_t)$ summarize the channel and buffer states for the next τ slots. Note that $\Gamma(\ell - 1, \mathbf{s}_t) \leq d(r_t) < \Gamma(\ell, \mathbf{s}_t)$ means that we can probably transmit all the data up to the ℓ^{th} layer in the next τ slots. Intuitively, we can simply choose $L^{\text{sch}}(\mathbf{s}_t) = \ell - 1$ when $\Gamma(\ell - 1, \mathbf{s}_t) \leq d(r_t) < \Gamma(\ell, \mathbf{s}_t)$. As discussed next, this layer selection scheme can be motivated by the near-optimal scheduling policies computed for the MDP-based model.

Note that $r_t = x_t(1 - y_t)$ is determined by state $\mathbf{s}_t$, thus $d(r_t)$ can also be written as function of $\mathbf{s}_t$, i.e., $d(\mathbf{s}_t)$. Suppose we partition the state space into subsets $\mathcal{P}^\ell = \{\mathbf{s} \in \mathcal{S} : \Gamma(\ell - 1, \mathbf{s}) \leq d(\mathbf{s}) < \Gamma(\ell, \mathbf{s})\}$, $\ell \in \{1, \dots, L + 1\}$ ⁴ and calculate the fraction of states in $\mathcal{P}^\ell$ where the MDP-based policy

³The relaxation time is defined as the temporal distance at which the temporal correlation coefficient is reduced to $\frac{1}{e}$

⁴We define $\Gamma(L + 1, \mathbf{s}_t) = +\infty$

only schedules the first $\ell - 1$ layers. As shown in Fig. 6, for 70% of the states of $\mathcal{P}^1$ and $\mathcal{P}^2$, the MDP-based policy only schedules the first layer. For about 65% of the states of $\mathcal{P}^3$, the MDP-based policy only schedules the first 2 layers. Finally the MDP-based policy will schedule all the layers on 65% of the states in $\mathcal{P}^4$. These observations justify our intuition regarding layer selection. In our proposed on-line scheduling algorithm, we will simply choose $L^{\text{sch}}(\mathbf{s}_t) = \ell - 1$ if $\Gamma(\ell - 1, \mathbf{s}_t) \leq d(r_t) < \Gamma(\ell, \mathbf{s}_t)$. In other words, our heuristic algorithm determines $L^{\text{sch}}(\mathbf{s}_t)$ by roughly estimating the number of layers which can be transmitted.

C. Resource allocation between current and future GoPs

In each transmission slot, r_t bits of video data are delivered to the receiver. In the following, we refer to r_t as the budget for slot t . Once $L^{\text{sch}}(\mathbf{s}_t)$ is determined, we still need to determine how to allocate this budget among $\mathcal{I}^{\text{pre}}$, $\mathcal{I}$ and $\mathcal{I}^{\text{post}}$. Sometimes it is necessary to transmit data associated with next I frame before the data units in the current GoP. For example, when the next I frame is approaching its display deadline and its base layer has not yet been received, if we focus on transmitting the frames in the current GoP sequentially, this increases the risk that the next I frame can not be decoded before its deadline. This in turn would cause severe decoding failures throughout the next GoP.

We denote by $\Psi^{\text{pre}}(\ell, \mathbf{s}_t)$ the amount of unreceived data in the first ℓ^{th} layer of $\mathcal{I}^{\text{pre}}$ at state $\mathbf{s}_t$. We denote by $\Psi^{\text{I}}(\ell, \mathbf{s}_t)$ the amount of unreceived data in the first ℓ^{th} layer of $\mathcal{I}$ at state $\mathbf{s}_t$. We propose the following heuristic for allocating the bit budget between $\mathcal{I}^{\text{pre}}$ and $\mathcal{I}$. In each transmission slot, the scheduling algorithm allocates up to $\Omega_t = \frac{\Psi^{\text{I}}(L^{\text{sch}}(\mathbf{s}_t), \mathbf{s}_t)}{\Psi^{\text{pre}}(L^{\text{sch}}(\mathbf{s}_t), \mathbf{s}_t) + \Psi^{\text{I}}(L^{\text{sch}}(\mathbf{s}_t), \mathbf{s}_t)}$ of the transmission bit budget to $\mathcal{I}$. In other words, the number of bits allocated to $\mathcal{I}$ is $\min(\Omega_t \times r_t, \Psi^{\text{I}}(L^{\text{sch}}(\mathbf{s}_t), \mathbf{s}_t))$.

Here Ω_t gives the relative importance of the next I frame and current GoP. If $\Psi^{\text{I}}(L^{\text{sch}}(\mathbf{s}_t), \mathbf{s}_t) = 0$, then $\Omega_t = 0\%$. It is not necessary to transmit any data for the next I frame. If $\Psi^{\text{pre}}(L^{\text{sch}}(\mathbf{s}_t), \mathbf{s}_t) = 0$, then $\Omega_t = 100\%$. We only focus on transmitting the future GoPs.

The online scheduling algorithm is summarized in Algorithm 1.

D. Performance evaluation of the on-line scheduling algorithm

The performance of the on-line scheduling algorithm was tested over the simulated Markov channel models with different Doppler frequencies ($f_d = 5\text{Hz}$ and 3Hz , respectively). This setting is the same as the simulation setting in Section III-F. The results are summarized in Fig. 7. As can be seen, the performance of the proposed online-scheduling algorithm is almost as good as the MDP-based scheduling algorithm. Moreover the online scheduling algorithm's performance is close to the bound given by Theorem 2. We conclude it is a near-optimal scheduling algorithm.

Algorithm 1 On-line adaptive scheduling algorithm

Input: $\mathbf{s}_t$, r_{avg} , r_t and ρ

```

1:  $\tau = \lceil -(\ln \rho)^{-1} \rceil$ 
2: loop  $t$ 
3:    $d(r_t) \leftarrow \sum_{j=0}^{\tau-1} [r_t \rho^j + r_{avg}(1 - \rho^j)]$  ▷ Channel estimation
4:   for  $\ell = 1 \rightarrow L$  do ▷ Determine  $L^{\text{sch}}(\mathbf{s}_t)$ 
5:     Compute  $\Gamma(\ell, \mathbf{s}_t)$ 
6:     if  $d(r_t) < \Gamma(\ell, \mathbf{s}_t)$  then
7:       break
8:     end if
9:   end for
10:  if  $\ell=1$  then
11:     $L^{\text{sch}}(\mathbf{s}_t) \leftarrow 1$ 
12:  else
13:     $L^{\text{sch}}(\mathbf{s}_t) \leftarrow \ell - 1$ 
14:  end if
15:  Compute  $\Psi^{\text{pre}}(L^{\text{sch}}, \mathbf{s}_t)$  and  $\Psi^{\text{I}}(L^{\text{sch}}, \mathbf{s}_t)$ 
16:   $\Omega_t \leftarrow \frac{\Psi^{\text{I}}(L^{\text{sch}}, \mathbf{s}_t)}{\Psi^{\text{pre}}(L^{\text{sch}}, \mathbf{s}_t) + \Psi^{\text{I}}(L^{\text{sch}}, \mathbf{s}_t)}$ 
17:  Schedule  $\min(\Omega_t \times r_t, \Psi^{\text{I}}(L^{\text{sch}}, \mathbf{s}_t))$  bits from  $\mathcal{I}$ . ▷ Scheduling data
18:  Schedule  $r_t - \min(\Omega_t \times r_t, \Psi^{\text{I}}(L^{\text{sch}}, \mathbf{s}_t))$  bits from  $\mathcal{I}^{\text{pre}}$  and  $\mathcal{I}^{\text{post}}$ .
19: end loop

```

According to our MDP model in Section III, the MDP-based optimal scheduling policy is supposed to be optimal among all considered scheduling policies. However, for the test video sequence “flower”, the online-scheduling algorithm even outperforms the MDP-based policy. That is due to the fact that the MDP-based scheduling policy is derived based on the rate quality model in Section II-C which assumes average rate quality characteristics of all frames. The online algorithm schedules data units according to $\Gamma(\ell, \mathbf{s}_t)$ using actual size of data units rather than the rate distortion model. Therefore, the online algorithm tends to estimate the buffer states more accurately, thus may result in better performance.

We have also tested the performance of the online algorithm without bit budget allocation between current and future GoPs. As can be seen, the performance is worse than the MDP-based scheduling

policy and the performance bound. This motivates the necessity of allocating bit between current and future GoPs.

V. CONCLUSIONS

We have developed adaptive scheduling algorithms for efficient scalable video transmission in wireless channels. By modeling the wireless channel as a Markov chain, an MDP model is proposed in which policies that maximize the visual quality predicted by MS-SSIM index can be computed. By simplifying the scheduling algorithm obtained from the MDP formulation, we propose an online scheduling algorithm which only requires limited knowledge of channel dynamics. Simulation results demonstrate the near-optimality of the proposed online scheduling policy versus a proposed bound on performance.

APPENDIX A

TRANSITION PROBABILITY

Notations: Let $\mathbf{1}$ is the unit vector of all-ones and $\mathbf{0}$ is the zero vector. $\max\{\mathbf{a}, \mathbf{b}\}$ and $\min\{\mathbf{a}, \mathbf{b}\}$ are the componentwise maximum and minimum of vector $\mathbf{a}$ and $\mathbf{b}$, respectively. $\mathbb{1}(\cdot)$ is the indicator function.

Let $\mathbf{s}_t = (\mathbf{c}_t, \mathbf{v}_t)$ and $\mathcal{U}_{\mathbf{s}_t}$ be the system state and the corresponding feasible control set at slot t , where $\mathbf{c}_t = (x_t, y_t)$ and $\mathbf{v}_t = (\mathbf{v}_t^{\text{pre}}, \mathbf{v}_t^I, \mathbf{v}_t^{\text{post}})$. At the beginning of each slot, one frame is decoded and played out. We let $\mathbf{v}_t^+ = (\mathbf{v}_t^{\text{pre}+}, \mathbf{v}_t^{I+}, \mathbf{v}_t^{\text{post}+})$ denote the buffer state right after the first frame is displayed. If $f_t^I = 1$, i.e., the decoded frame is an I frame, then the frame set $\mathcal{I}$ becomes the next I frame, i.e., the F_{GOP}^{th} frame. Hence, the buffer state is

$$\mathbf{v}_t^{I+} = \left(F_{GOP}, \sum_{\ell=1}^L \mathbb{1}(b_\ell^{\text{post}} \geq F_{GOP}) \right), \quad (17)$$

where $\sum_{\ell=1}^L \mathbb{1}(b_\ell^{\text{post}} \geq F_{GOP})$ is the number of received layers in the next I frame. Meanwhile, $\mathcal{I}^{\text{pre}}$ becomes the first $F_{GOP} - 1$ frames and $\mathcal{I}^{\text{post}}$ contains the frames whose index is larger than F_{GOP} . Thus, we have

$$\mathbf{v}_t^{\text{pre}+} = \min \left\{ \mathbf{v}_t^{\text{post}}, (F_{GOP} - 1)\mathbf{1} \right\} \quad (18)$$

and

$$\mathbf{v}_t^{\text{post}+} = \max \left\{ \mathbf{v}_t^{\text{post}} - F_{GOP}\mathbf{1}, \mathbf{0} \right\}. \quad (19)$$

If the decoded frame is not an I frame, the frame set $\mathcal{I}^{\text{post}}$ will not be affected and the buffer state $\mathbf{v}_t^{\text{post}}$ does not change. $\mathbf{v}_t^{\text{pre}}$ becomes

$$\mathbf{v}_t^{\text{pre}+} = \max \left\{ \mathbf{v}_t^{\text{pre}} - \mathbf{1}, \mathbf{0} \right\}. \quad (20)$$

Summarizing (17), (18), (19) and (20), we have

$$\mathbf{v}_t^{\text{pre}+} = \begin{cases} \min \{ \mathbf{v}_t^{\text{post}}, (F_{GOP} - 1)\mathbf{1} \} & \text{if } f_t^I = 1, \\ \max \{ \mathbf{v}_t^{\text{pre}} - \mathbf{1}, \mathbf{0} \} & \text{if } f_t^I \neq 1, \end{cases}$$

$$\mathbf{v}_t^{I+} = \begin{cases} (F_{GOP}, \sum_{\ell=1}^L \mathbb{1}(b_\ell^{\text{post}} \geq F_{GOP})) & \text{if } f_t^I = 1, \\ (f_t^I - 1, \ell_t^I) & \text{if } f_t^I \neq 1, \end{cases}$$

and

$$\mathbf{v}_t^{\text{post}+} = \begin{cases} \max \{ \mathbf{v}_t^{\text{post}} - F_{GOP}\mathbf{1}, \mathbf{0} \} & \text{if } f_t^I = 1, \\ \mathbf{v}_t^{\text{post}} & \text{if } f_t^I \neq 1. \end{cases}$$

After the first frame is displayed, the transmitter begins to sequentially transmit the collection of video data units indicated by the action $\mathcal{U}_t = \mu(\mathbf{s}_t) = \{(f_1, \ell_1), \dots, (f_{|\mathcal{U}_t|}, \ell_{|\mathcal{U}_t|})\}$. Let $\Delta\mathcal{U}_t = \{(f_1, \ell_1), \dots, (f_{n_t}, \ell_{n_t})\}$ denote the completely received data units by the end of the slot, where n_t is the number of received data units. Among the data units in $\Delta\mathcal{U}_t$, let $\Delta\mathbf{v}_t^{\text{pre}} = (\Delta b_1^{\text{pre}}, \Delta b_2^{\text{pre}}, \dots, \Delta b_L^{\text{pre}})$ be the number of newly received data units for each layer in frame set $\mathcal{I}^{\text{pre}}$. Similarly, we denote $\Delta\mathbf{v}_t^{\text{post}} = (\Delta b_1^{\text{post}}, \Delta b_2^{\text{post}}, \dots, \Delta b_L^{\text{post}})$ as the number of newly received data units for each layer in frame set $\mathcal{I}^{\text{post}}$ and $\Delta\ell^I$ as the number of received data units for $\mathcal{I}$. At the beginning of the $(t+1)^{\text{th}}$ slot, we have the following state transition relationship

$$\mathbf{v}_{t+1}^{\text{pre}} = \mathbf{v}_t^{\text{pre}+} + \Delta\mathbf{v}_t^{\text{pre}}, \quad (21)$$

$$\mathbf{v}_{t+1}^I = (f_t^{I+}, \ell_t^{I+} + \Delta\ell^I), \quad (22)$$

$$\mathbf{v}_{t+1}^{\text{post}} = \mathbf{v}_t^{\text{post}+} + \Delta\mathbf{v}_t^{\text{post}}. \quad (23)$$

The amount of video data in $\Delta\mathcal{U}_t$, denoted by $\Phi(\mathbf{v}_t, \Delta\mathcal{U}_t)$, can be estimated according to buffer state $\mathbf{v}_t^I$ and the rate-quality model introduced in Section II-C. Specifically, for each data unit in $\Delta\mathcal{U}_t$, we first determine whether it belongs to an I frame or a P frame according to $\mathbf{v}_t^I$ and then estimate the amount of data by the rate-quality model. The set $\Delta\mathcal{U}_t$ records the completely transmitted data units up to $(f_{n_t}, \ell_{n_t})^{\text{th}}$ data unit. However, data unit $(f_{n_t+1}, \ell_{n_t+1})$ is only partially received. Denoting the amount of data in unit $(f_{n_t+1}, \ell_{n_t+1})$ by $\tilde{\Phi}(\mathbf{v}_t^I, \Delta\mathcal{U}_t)$, the amount of received data is at least $\Phi(\mathbf{v}_t^I, \Delta\mathcal{U}_t)$ and at most $\Phi(\mathbf{v}_t^I, \Delta\mathcal{U}_t) + \tilde{\Phi}(\mathbf{v}_t^I, \Delta\mathcal{U}_t)$. Assuming the physical layer packet length is L_{PHY} , there is $N = \lceil \frac{x_t}{L_{PHY}} \rceil$ packet transmissions during a time slot. The number of successfully transmitted packets is at least $N_l = \lceil \frac{\Phi(\mathbf{v}_t^I, \Delta\mathcal{U}_t)}{L_{PHY}} \rceil$ and is less than $N_h = \lceil \frac{\Phi(\mathbf{v}_t^I, \Delta\mathcal{U}_t) + \tilde{\Phi}(\mathbf{v}_t^I, \Delta\mathcal{U}_t)}{L_{PHY}} \rceil$. As assumed in Section II-D, the channel state is constant over each slot. Thus, the packet losses are independent within each slot.

The number of successful packet transmissions in a slot is distributed binomially. Hence, the state transition probability from $\mathbf{s}_t = (\mathbf{c}_t, \mathbf{v}_t)$ to $\mathbf{s}_{t+1} = (\mathbf{c}_{t+1}, \mathbf{v}_{t+1})$ is

$$\mathbb{P}_\mu(\mathbf{s}_{t+1}|\mathbf{s}_t) = \left[\sum_{n_t=N_l}^{N_h-1} \binom{N}{n_t} y_t^{N-n_t} (1-y_t)^{n_t} \right] \mathbb{P}(\mathbf{c}_t, \mathbf{c}_{t+1}), \quad (24)$$

where the first multiplicative term is the transition probability of the receiver buffer state from $\mathbf{v}_t$ to $\mathbf{v}_{t+1}$ and the second term is the transition probability of the channel state from $\mathbf{c}_t$ to $\mathbf{c}_{t+1}$.

APPENDIX B

COMPUTATION OF t_μ AND $\tilde{\mathbb{P}}_\mu$

Let $v_t^{\overline{W}}$ be the number of buffered packets outside the window. Noted that, when the system moves in $\mathcal{S}_{\overline{W}}$, the system always schedules as many enhancement layer data units as possible. Hence, $v_t^{\overline{W}}$ and f_t^I contain all the information about the buffer state $\mathbf{v}_t$. We can further simplify the state representation $(\mathbf{c}_t, \mathbf{v}_t)$ to $(\mathbf{c}_t, v_t^{\overline{W}}, f_t^I)$ when $(\mathbf{c}_t, \mathbf{v}_t) \in \mathcal{S}_{\overline{W}}$. All the states in $\mathcal{S}_{\overline{W}}$ correspond to some states with $v_t^{\overline{W}} \geq 0$. All the states in $\mathcal{S}_W$ correspond to some states with $v_t^{\overline{W}} < 0$.

When the system evolves in $\mathcal{S}_{\overline{W}}$, at the beginning of a slot t , the state $v_t^{\overline{W}}$ first decreases by $\Delta v_{\text{dec}}^{\overline{W}}(\mathbf{s}_t)$ when the current frame is displayed. Then, the transmitter schedules as many enhancement layer data units as possible. At the end of the slot, $v_t^{\overline{W}}$ increases by $\Delta v_{\text{inc}}^{\overline{W}}(\mathbf{s}_t)$. Because the quantity $\Delta v^{\overline{W}}(\mathbf{s}_t) = \Delta v_{\text{inc}}^{\overline{W}}(\mathbf{s}_t) - \Delta v_{\text{dec}}^{\overline{W}}(\mathbf{s}_t)$ only depends on state $\mathbf{s}_t$, the state $v_t^{\overline{W}}$ varies like a random walk but with Markovian step-size $\Delta v^{\overline{W}}(\mathbf{s}_t)$. Now we need to compute, given the starting state $\mathbf{s}_t$ with $v_t^{\overline{W}} \geq 0$, how long it takes to jump to a state where $v_t^{\overline{W}} < 0$. Let $\Delta v_{\text{max}}^{\overline{W}} = \max_{\mathbf{s} \in \mathcal{S}_{\overline{W}}} \{|\Delta v^{\overline{W}}(\mathbf{s})|\}$ be the maximum step size. We define the k th level set as

$$\mathcal{S}_k = \mathcal{C} \times \{k\Delta v_{\text{max}}^{\overline{W}} + 1, \dots, (k+1)\Delta v_{\text{max}}^{\overline{W}}\} \times \{1, \dots, F_{\text{GOP}}\}, \quad (25)$$

where $k \geq -1$. After the system moves to $\mathcal{S}_{\overline{W}}$, the system state transits in level set $\mathcal{S}_k$ with $k \geq 0$ and then jumps to a state in $\mathcal{S}_{-1}$. If we concatenate all these level set as $\mathcal{S}_{\mathcal{K}} = \cup_{k=-1}^{\infty} \mathcal{S}_k$, then the state transition matrix is a banded infinite matrix of the following form

$$\begin{bmatrix} \mathbf{B}_0 & \mathbf{B}_1 & & & \\ \mathbf{A}_0 & \mathbf{A}_1 & \mathbf{A}_2 & & \\ & \mathbf{A}_0 & \mathbf{A}_1 & \mathbf{A}_2 & \\ & & \mathbf{A}_0 & \mathbf{A}_1 & \ddots \\ & & & \ddots & \ddots \end{bmatrix}.$$

The blocks $\mathbf{B}_0, \mathbf{B}_1, \mathbf{A}_0, \mathbf{A}_1$ and $\mathbf{A}_2$ are all square matrices of dimension $d = |\mathcal{C}| \Delta v_{\max}^{\overline{W}} F_{GOP}$. When the system state jumps to $\mathcal{S}_\Delta$, the state lies in level set $\mathcal{S}_0$. Now we need to compute how long the system takes to reach $\mathcal{S}_{-1}$ for the first time. This problem of continuous time quasi-birth-death processes was essentially solved by Neuts in the early 1980s [26]. The following derivation follows similarly the one in Neuts' book but for the discrete time case.

Let $G^\nu(k, x)_{j,j'}$ be the probability that, starting from the j th state in level set $\mathcal{S}_n$, the system state hits level set $\mathcal{S}_{(n-v)}$ for the first time after x movements in which there are k left movements. The hitting point is the j' th state in $\mathcal{S}_{(n-v)}$. Let $\mathbf{G}^\nu(k, x)$ be the $d \times d$ matrix with $G^\nu(k, x)_{j,j'}$ as the (j, j') entry. Applying the Z transform to this distribution we have

$$\hat{\mathbf{G}}^{(\nu)}(z, s) = \sum_{k=0}^{\infty} z^k \left(\sum_{x=0}^{\infty} \mathbf{G}(k, x)^{(\nu)} s^x \right). \quad (26)$$

Denoting $\hat{\mathbf{G}}^{(1)}(z, s)$ by $\hat{\mathbf{G}}(z, s)$, it can be proved that $\hat{\mathbf{G}}^{(\nu)}(z, s) = (\hat{\mathbf{G}}(z, s))^\nu$ [26]. Conditioning on the state visited in the first state transition, we have

$$\hat{\mathbf{G}}(z, s) = \mathbf{A}_0 z s + \mathbf{A}_1 \hat{\mathbf{G}}(z, s) s + \mathbf{A}_2 \hat{\mathbf{G}}^2(z, s) s. \quad (27)$$

Now, define $\mathbf{G} = \hat{\mathbf{G}}(1, 1)$, $\mathbf{C}_0 = (\mathbf{I} - \mathbf{A}_1)^{-1} \mathbf{A}_0$, $\mathbf{C}_1 = (\mathbf{I} - \mathbf{A}_1)^{-1}$ and $\mathbf{C}_2 = (\mathbf{I} - \mathbf{A}_1)^{-1} \mathbf{A}_2$. By simple matrix manipulation of (27), we have

$$\mathbf{G} = \mathbf{C}_0 + \mathbf{C}_2 \mathbf{G}^2. \quad (28)$$

We can compute $\mathbf{G}$ by successive substitutions starting with the zero matrix. Because $\mathbf{G} = \hat{\mathbf{G}}(z, s)|_{z=1, s=1}$, its entry $\mathbf{G}_{j,j'}$ is actually the conditional probability that, given the initial state $j \in \mathcal{S}_0$, the system will move to $\mathcal{S}_{-1}$ for the first time at the j' th state. Hence, we can find $\tilde{\mathbb{P}}_\mu(\cdot|\cdot)$ from $\mathbf{G}$.

Let $\mathbf{M} = \frac{d\hat{\mathbf{G}}(z, s)}{ds}|_{z=1, s=1}$. The (j, j') th entry $\mathbf{M}_{j,j'} = \sum_{k=0}^{\infty} \sum_{x=0}^{\infty} (x \mathbf{G}_{j,j'}(k, x))$ is the conditional expectation of the time that, given the initial state $j \in \mathcal{S}_0$, the system takes to hit $\mathcal{S}_{-1}$ for the first time at the j' th state. Differentiating both sides of (27) with respect to s , then setting $s = 1$, $z = 1$, we have

$$\mathbf{M} = \mathbf{A}_0 + \mathbf{A}_1 \mathbf{M} + \mathbf{A}_1 \mathbf{G} + \mathbf{A}_2 \mathbf{G}^2 + \mathbf{A}_2 (\mathbf{G} \mathbf{M} + \mathbf{M} \mathbf{G}). \quad (29)$$

Using the definition of $\mathbf{C}_1$ and $\mathbf{C}_2$, equation (29) can be simplified as

$$\mathbf{M} = \mathbf{C}_1 \mathbf{G} + \mathbf{C}_2 (\mathbf{G} \mathbf{M} + \mathbf{M} \mathbf{G}). \quad (30)$$

We can compute $\mathbf{M}$ by successive substitutions starting with the zero matrix. We define a vector

$$\mathbf{t} = \mathbf{M} \mathbf{1}. \quad (31)$$

The j th entry $t_j = \sum_{j'=0}^D \sum_{k=0}^{\infty} \sum_{x=0}^{\infty} (x \mathbf{G}_{j,j'}(k, x))$ is the conditional expectation of the time that the system takes to go back to $\mathcal{S}_{-1}$ given the initial state $j \in \mathcal{S}_0$, i.e., $t_\mu(j)$. Therefore, we can compute t_μ and $\tilde{\mathbb{P}}_\mu$ using (28) and (31).

APPENDIX C

SIMULATION SETTINGS

We employ the FSMC channel model proposed in [16] to model the dynamics of Rayleigh fading channels. The SNR at the receiver is partitioned into $|\mathcal{C}|$ regions using the algorithm proposed in [16]. Let Λ_i be the partition thresholds, where $\Lambda_0 = -\infty$ and $\Lambda_{|\mathcal{C}|} = \infty$. Let $\tilde{\Lambda}_k$ be the representative SNR in the k^{th} region. For Rayleigh fading channels, we have

$$\tilde{\Lambda}_k = \frac{\int_{\Lambda_{k-1}}^{\Lambda_k} \lambda p(\lambda) d\lambda}{\int_{\Lambda_{k-1}}^{\Lambda_k} p(\lambda) d\lambda}, \quad (32)$$

where $p(\lambda) = \frac{1}{\Lambda_{avg}} \exp(-\frac{\lambda}{\Lambda_{avg}})$ is the probability distribution function of the received instantaneous SNR of Rayleigh fading channels with average SNR Λ_{avg} . According to [16], the state transition probability $\mathbf{P}^c$ is computed as

$$\mathbf{P}_{i,j}^c = \begin{cases} \frac{\mathcal{K}(\Lambda_j)\Delta T}{\pi_i} & \text{if } j = i + 1, \\ \frac{\mathcal{K}(\Lambda_i)\Delta T}{\pi_i} & \text{if } j = i - 1, \\ 1 - \frac{\mathcal{K}(\Lambda_j)\Delta T}{\pi_i} - \frac{\mathcal{K}(\Lambda_i)\Delta T}{\pi_i} & \text{if } j = i, \\ 0 & \text{otherwise,} \end{cases}$$

where $\pi_i = \int_{\Lambda_{i-1}}^{\Lambda_i} p(\lambda) d\lambda$. $\mathcal{K}(\Lambda_i) = \sqrt{\frac{2\pi\Lambda_i}{\Lambda_{avg}}} f_d \exp(-\frac{\Lambda_i}{\Lambda_{avg}})$ is the level crossing rate of threshold Λ_i where f_d is the Doppler frequency. The coherence time is estimated via $t_{\text{cor}} = 0.423/f_d$. In our simulations, we set $|\mathcal{C}| = 4$ and $\Lambda_{avg} = 10\text{dB}$.

We assume that BPSK, QPSK and 8PSK are used for modulation. The symbol error rate p_k^s in the k^{th} SNR region is $p_k^s = 2Q(\sqrt{2\tilde{\Lambda}_k} \sin \frac{\pi}{2M})$, where $M = 1, 2, 3$ for BPSK, QPSK and 8PSK, respectively. Each packet contains 2048 symbols. Thus, the packet length $L_{PHY} = 2048 \times M$, where $M = 1, 2$ and 3 for BPSK, QPSK and 8PSK, respectively. The transmission time for each packet is $\Delta t = 1.5\text{ms}$. The transmission data rate is given by $x_k = \frac{\Delta T}{\Delta t} L_{PHY}$. The packet error rate is given by $y_k = 1 - (1 - p_k^s)^{2048}$. The modulation scheme for k^{th} channel states is chosen such that the throughput $x_k(1 - y_k)$ is maximized.

The proposed dynamic scheduling algorithm was evaluated on the test sequences “foreman”, “bus”, “flower”, “mobile” and “Paris” [23]. These video sequences were encoded using H.264/SVC reference

software JSVM [24] with 3 layers. The GOP length was fixed at $F_{GOP} = 16$. The encoding parameters and rate-quality model parameters are listed in Table II. The parameters r_ℓ^I and r_ℓ^P are measured in megabits and q^ℓ is measured in MS-SSIM index values. The quantization parameters (QP) were chosen such that the data rate of the base layer is lower than the average channel throughput. The Lagrangian multipliers for motion estimation and mode decision were set as $QP - 2$. We employ this configuration to make sure that the channel is at least good enough to support the base layer. Otherwise, any scheduling policy cannot provide acceptable visual quality.

TABLE I
FREQUENTLY USED NOTATION.

Notations	Descriptions
F_{GOP}	Number of frames in a GOP.
L	Number of layers.
z_t	The amount of received data for the frame that is played out in the t^{th} slot.
ω_ℓ^P and ω_ℓ^I	The amount of data in the ℓ^{th} layer of a P and an I frame, respectively.
q^ℓ	The visual quality increment when the ℓ^{th} layer is correctly received.
$q^I(z_t), q^P(z_t)$	The rate-quality model for I frames and P frames.
$\hat{q}^I(z_t), \hat{q}^P(z_t)$	The concave envelopes of $Q^I(z_t)$ and $Q^P(z_t)$.
X_t and Y_t	The transmission bit rate and the packet error rate at the t^{th} slot.
x_t and y_t	The realizations of X_t and Y_t .
R_t, r_t	$R_t = X_t(1 - Y_t)$ is the channel throughput, which is random. r_t is a realization of R_t .
r_{avg}	The average value of the channel throughput r_t over time.
C_t, V_t and S_t	The channel state, buffer state and system state at the t^{th} slot.
$\mathbf{c}_t, \mathbf{v}_t$ and $\mathbf{s}_t$	The realizations of C_t, V_t and S_t .
